

# A comparison of farm-scale models to estimate greenhouse gas emissions from dairy farms in Europe

Nick Hutchings, Michel De Haan  
Şeyda Özkan, Daniel Sandars

The MACSUR Science conference  
8-10 April 2015 Reading University UK

# Background

- Farm scale is essential when upscaling ruminant livestock production
  - significant flexibility in management
  - substantial internal nutrient cycling
- Farm models differ in:
  - Focus (production/economics/environment)
  - Purpose (supporting farmers/farm advisors, regulators)
- How would these differences affect results if the models were used to simulate the same dairy cattle farms?

# Models

- SFarMod
  - optimised management
  - emission factors
  - portable
  - 30+ years experience
- Dairywise
  - optimised feed supply
  - empirical emission factors
  - location-specific (Netherlands)
  - 10+ years of experience

# Models

- FarmAC
  - user inputs management
  - emission factors (except dynamic soil model)
  - portable
  - 1 year of experience
- HolosNor
  - user inputs management
  - emission factors
  - Canadian model, adapted for Norway
  - 2-3 years of experience

# Standard factorial scenarios

Warm x cool  
climate

Sandy x clay  
soil

Grass only x  
grass & maize

Dairy cows + followers (1:1)

600 kg LW & 7000 kg ECM/cow/yr

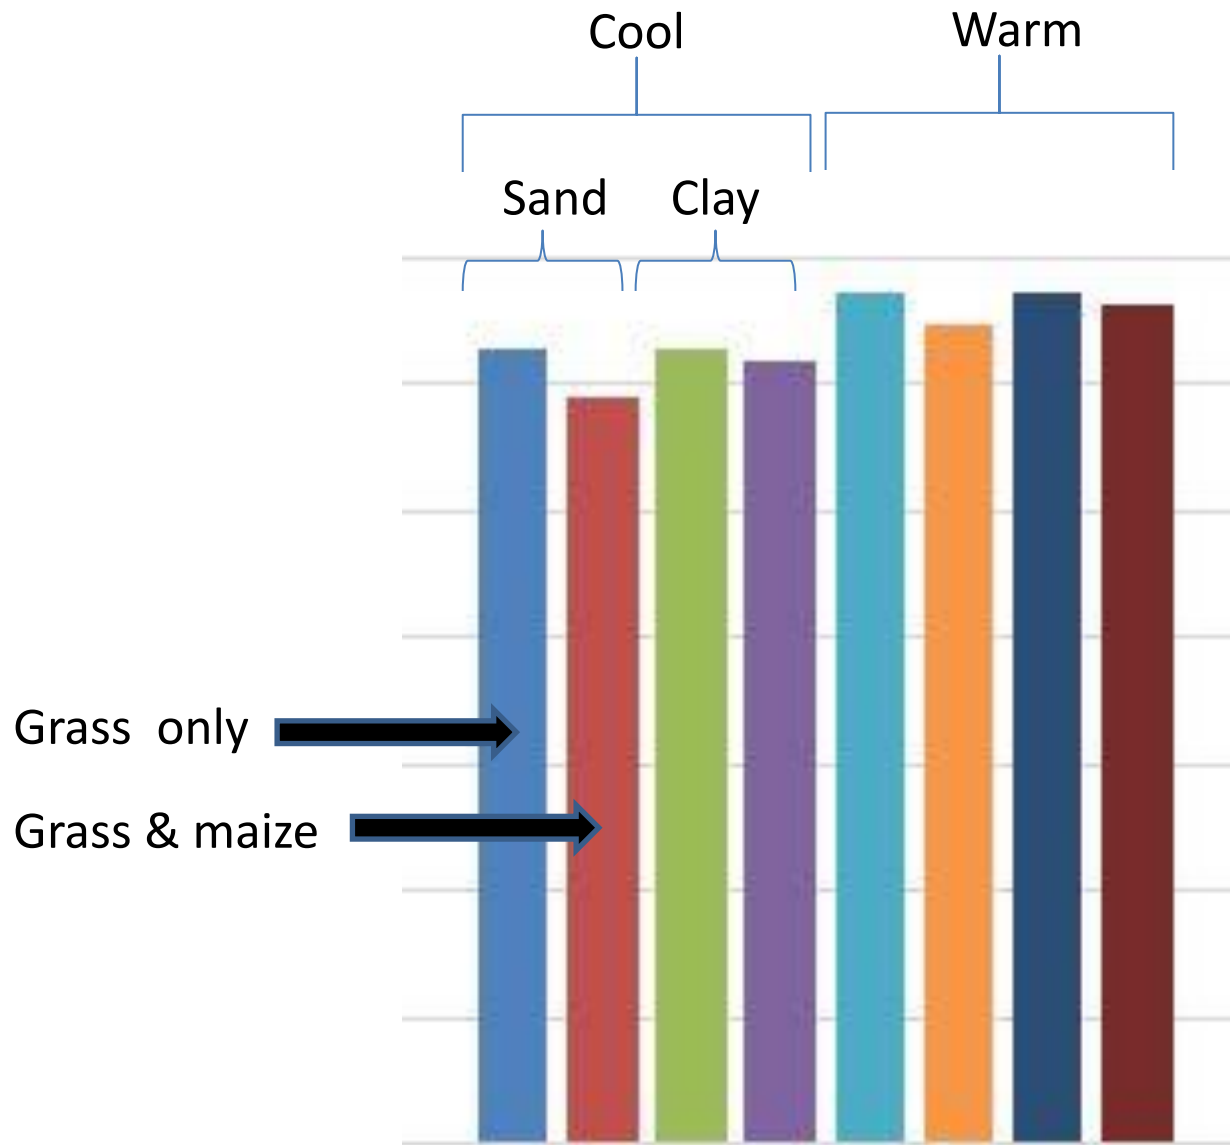

Cool climate grazing 5 months  
Warm climate grazing 10 months  
16 hours/day grazing

Minimum use of concentrates  
No manure import/export

Plant-available N:  
Grass 275 kg/ha/yr  
Maize 150 kg/ha/yr  
(Manure broadcast)

For each scenario, adjust cow  
numbers to match feed supply

# RESULTS

## Dairy cows per ha

HolosNor uses FarmAC livestock numbers

Differences in feed requirement models

For grass & maize - differences in area allocated to maize

## Total farm GHG emissions (Mg CO<sub>2</sub> e / ha)

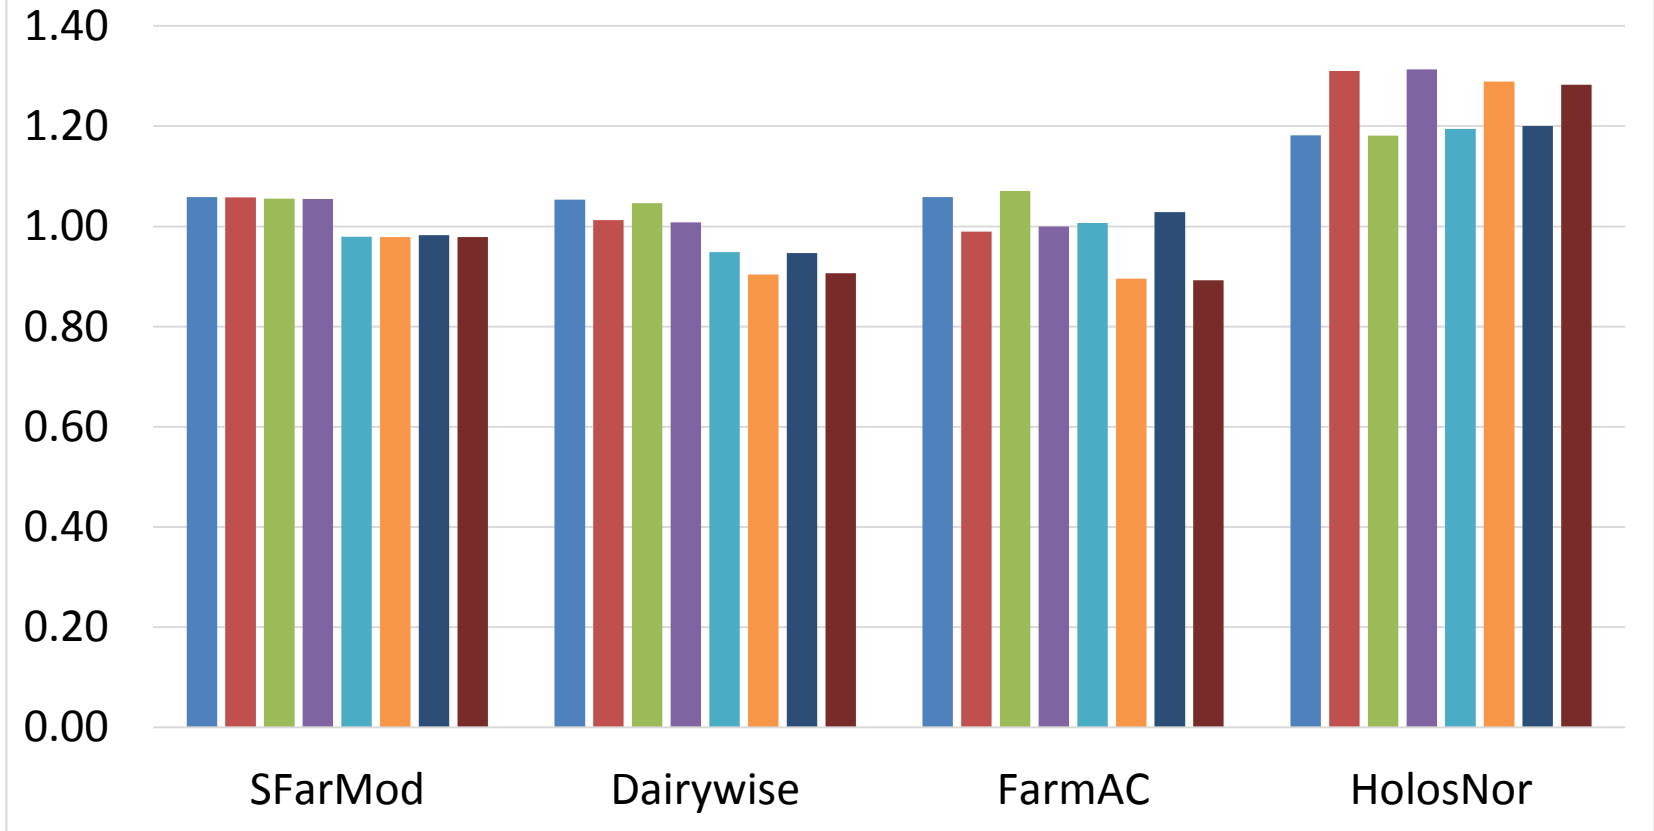

Note – pre-chain/post-chain not simulated

Grass only > grass & maize

Little effect of soil type – true for most variables

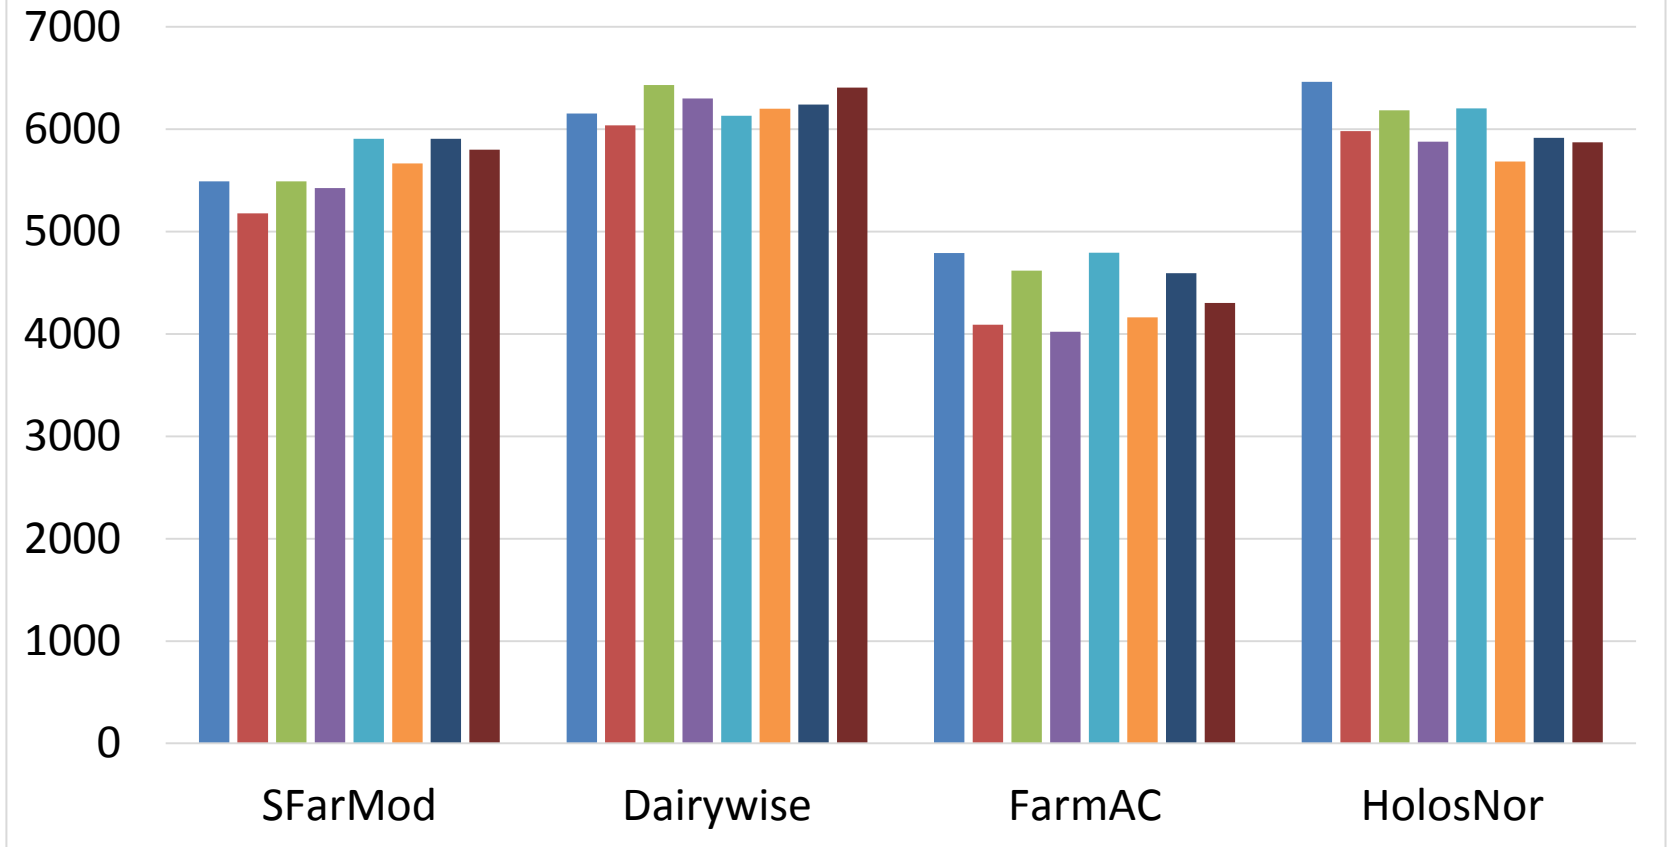

## Emission intensity (kg CO<sub>2</sub> e / kg ECM)

Cool climate > warm

Grass only > grass & maize (except HolosNor)

## Enteric methane emissions (kg CO<sub>2</sub> e / ha)

FarmAC low – feed requirement model predicts lower intake necessary to achieve 7000 litres milk/yr

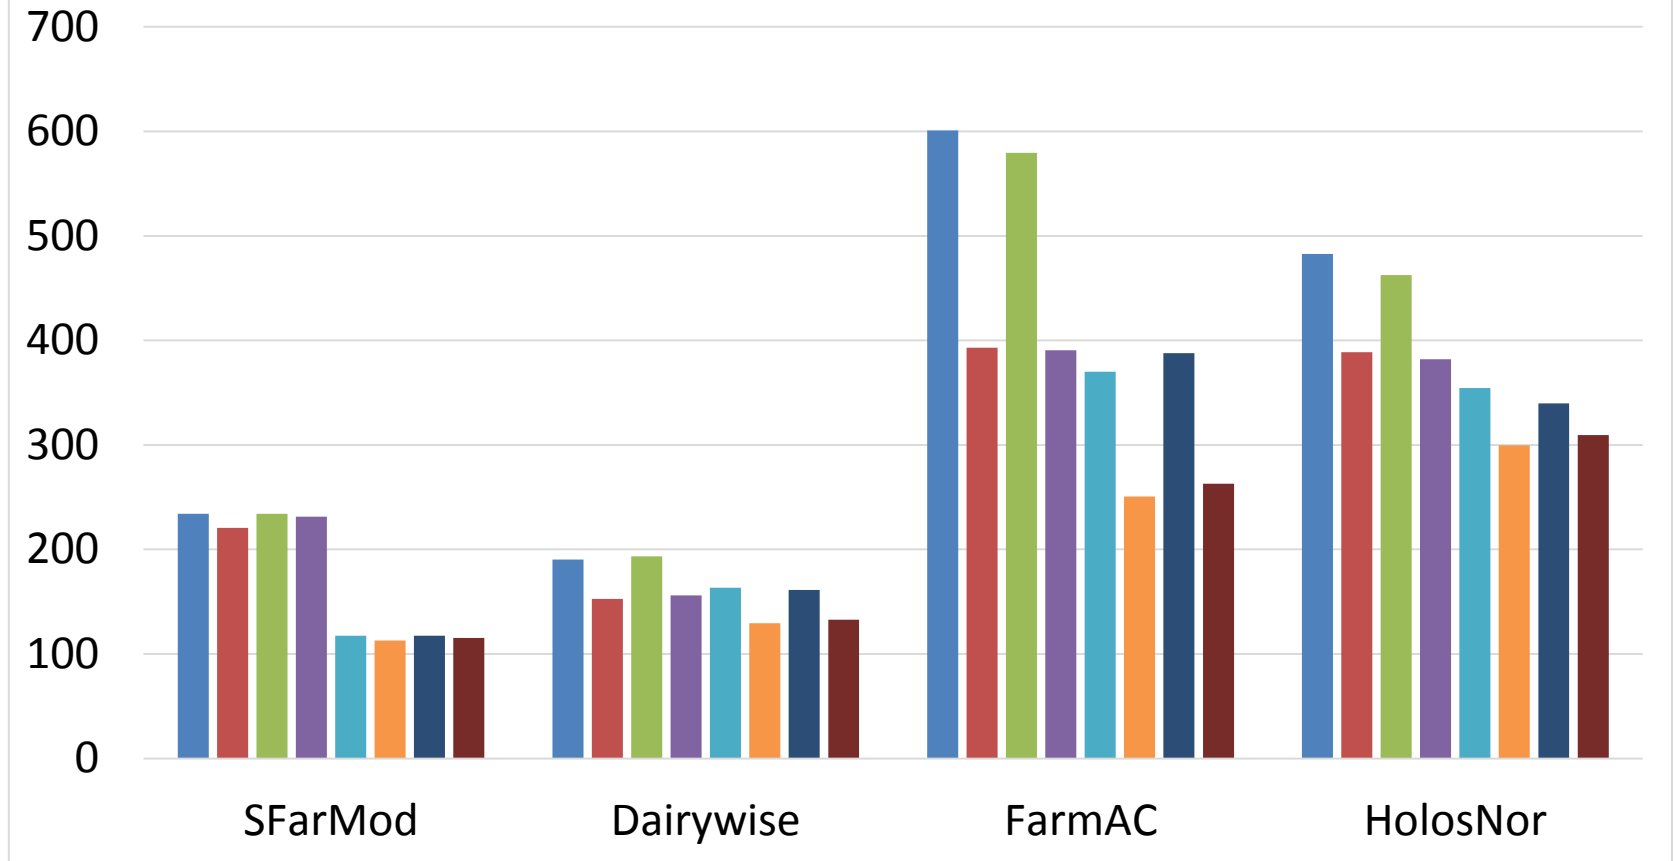

## Manure methane emissions (kg CO<sub>2</sub> e / ha)

Higher for cool climate (more manure produced in housing)

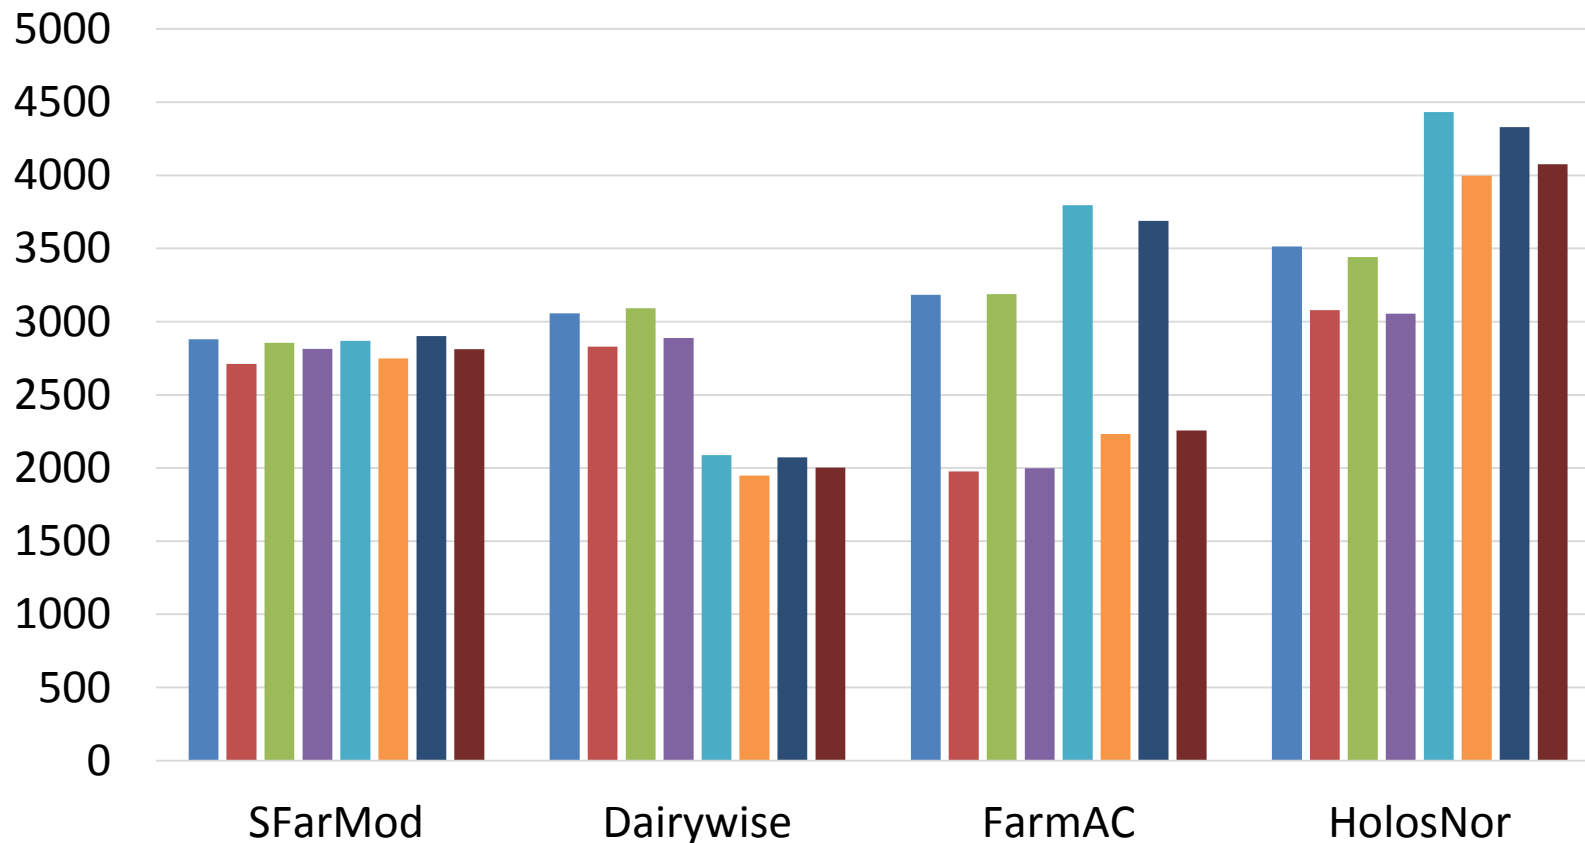

Dairywise imposes Netherlands manure regulations concerning manure storage

## Manure N<sub>2</sub>O emissions (kg CO<sub>2</sub> e / ha)

Higher for cool climate (more manure produced in housing)  
**but relationship between models differs relative to methane**

## Field N<sub>2</sub>O emissions (kg CO<sub>2</sub> e / ha)

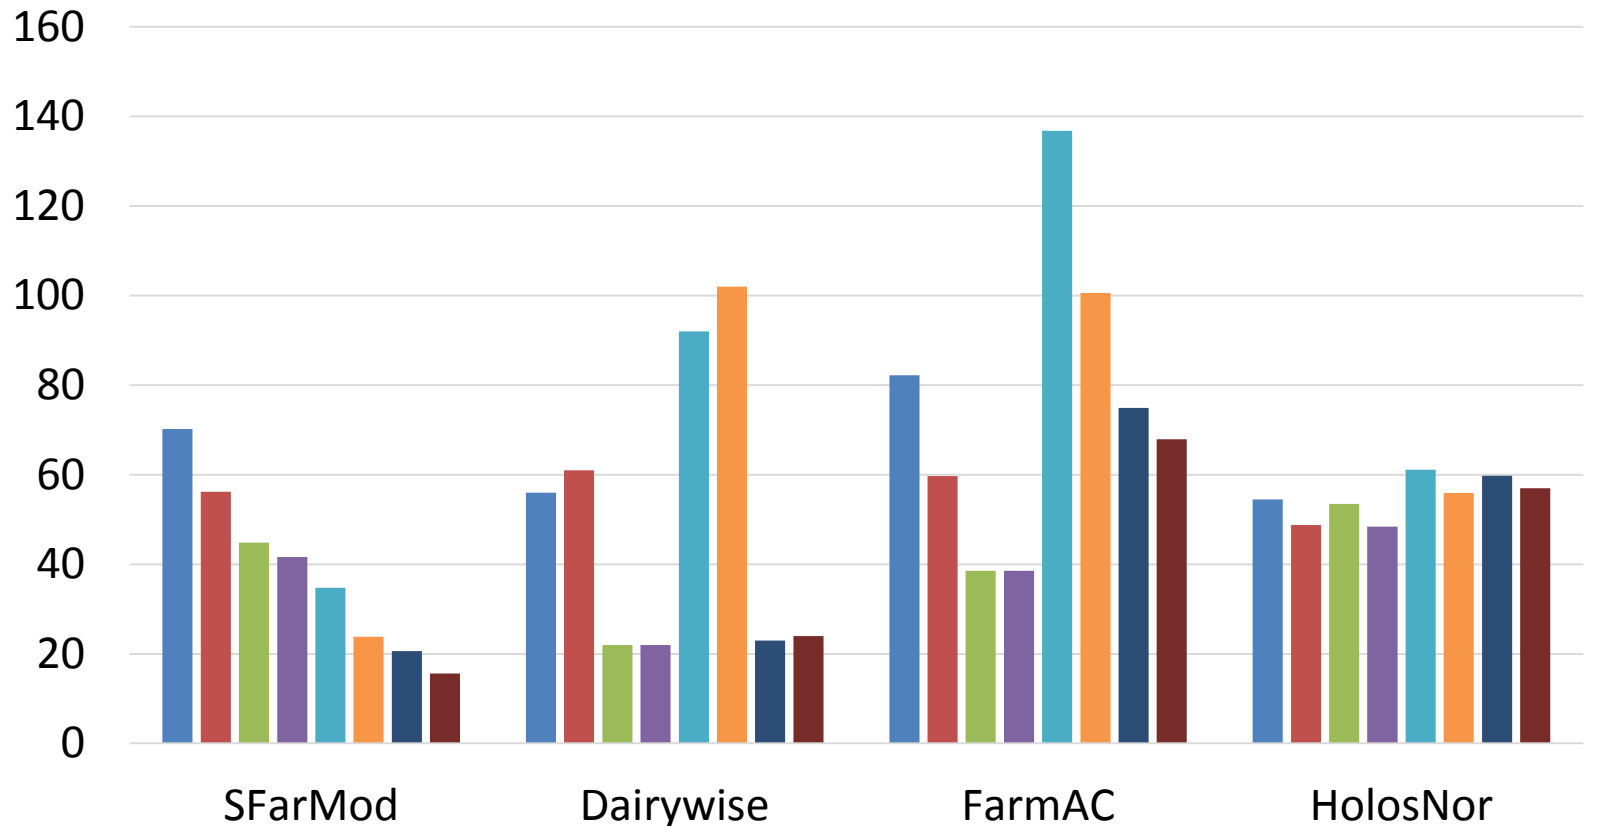

Differences between models in how they treat manure N and excretal N

## Total farm indirect GHG emissions (kg CO<sub>2</sub> e / ha)

Indirect = nitrous oxide emission resulting from nitrate leaching and ammonia emission

## NO<sub>3</sub> leaching (kg NO<sub>3</sub>-N / ha / year)

Large differences between models

Grass only > grass & maize

Effect of soil type in some models

## NH<sub>3</sub> emissions from field (kg NH<sub>3</sub>-N / ha / year)

Large differences between models (different emission factors)  
Grass only > grass & maize

# Conclusions (1)

- Total GHG emissions per kg milk and per ha were similar for all models
  - but this disguises some major differences between models
- Little effect of soil type
- All models tended to predict lower emissions for the warm climate
- More work necessary to understand the details of why models differ

# Conclusions (2)

- Assumptions concerning farm management are important
  - need for more empirical data and better understanding of processes
- If used to prioritise mitigation measures, these models would give very different answers
- It has been a useful learning exercise
